**Public Summary:**

In this publication, Barske et al show how stem cells are regulated in the developing face. In particular, they should how a type of cell-cell communication system, termed Jagged-Notch, maintains stem cells for longer in the upper face, thus giving it a distinctive shape from the lower face.

**Scientific Abstract:**

The intricate shaping of the facial skeleton is essential for function of the vertebrate jaw and middle ear. While much has been learned about the signaling pathways and transcription factors that control facial patterning, the downstream cellular mechanisms dictating skeletal shapes have remained unclear. Here we present genetic evidence in zebrafish that three major signaling pathways - Jagged-Notch, Endothelin1 (Edn1), and Bmp - regulate the pattern of facial cartilage and bone formation by controlling the timing of cartilage differentiation along the dorsoventral axis of the pharyngeal arches. A genomic analysis of purified facial skeletal precursors in mutant and overexpression embryos revealed a core set of differentiation genes that were commonly repressed by Jagged-Notch and induced by Edn1. Further analysis of the pre-cartilage condensation gene *barx1*, as well as in vivo imaging of cartilage differentiation, revealed that cartilage forms first in regions of high Edn1 and low Jagged-Notch activity. Consistent with a role of Jagged-Notch signaling in restricting cartilage differentiation, loss of Notch pathway components resulted in expanded *barx1* expression in the dorsal arches, with mutation of *barx1* rescuing some aspects of dorsal skeletal patterning in *jag1b* mutants. We also identified *prrx1a* and *prrx1b* as negative Edn1 and positive Bmp targets that function in parallel to Jagged-Notch signaling to restrict the formation of dorsal *barx1*+ pre-cartilage condensations. Simultaneous loss of *jag1b* and *prrx1a/b* better rescued lower facial defects of *edn1* mutants than loss of either pathway alone, showing that combined overactivation of Jagged-Notch and Bmp/*Prx1* pathways contribute to the absence of cartilage differentiation in the *edn1* mutant lower face. These findings support a model in which Notch-mediated restriction of cartilage differentiation, particularly in the second pharyngeal arch, helps to establish a distinct skeletal pattern in the upper face.
